

Can we use a recent quantitative  
structural characterisation of disordered foams  
for early detection of metastasis risk

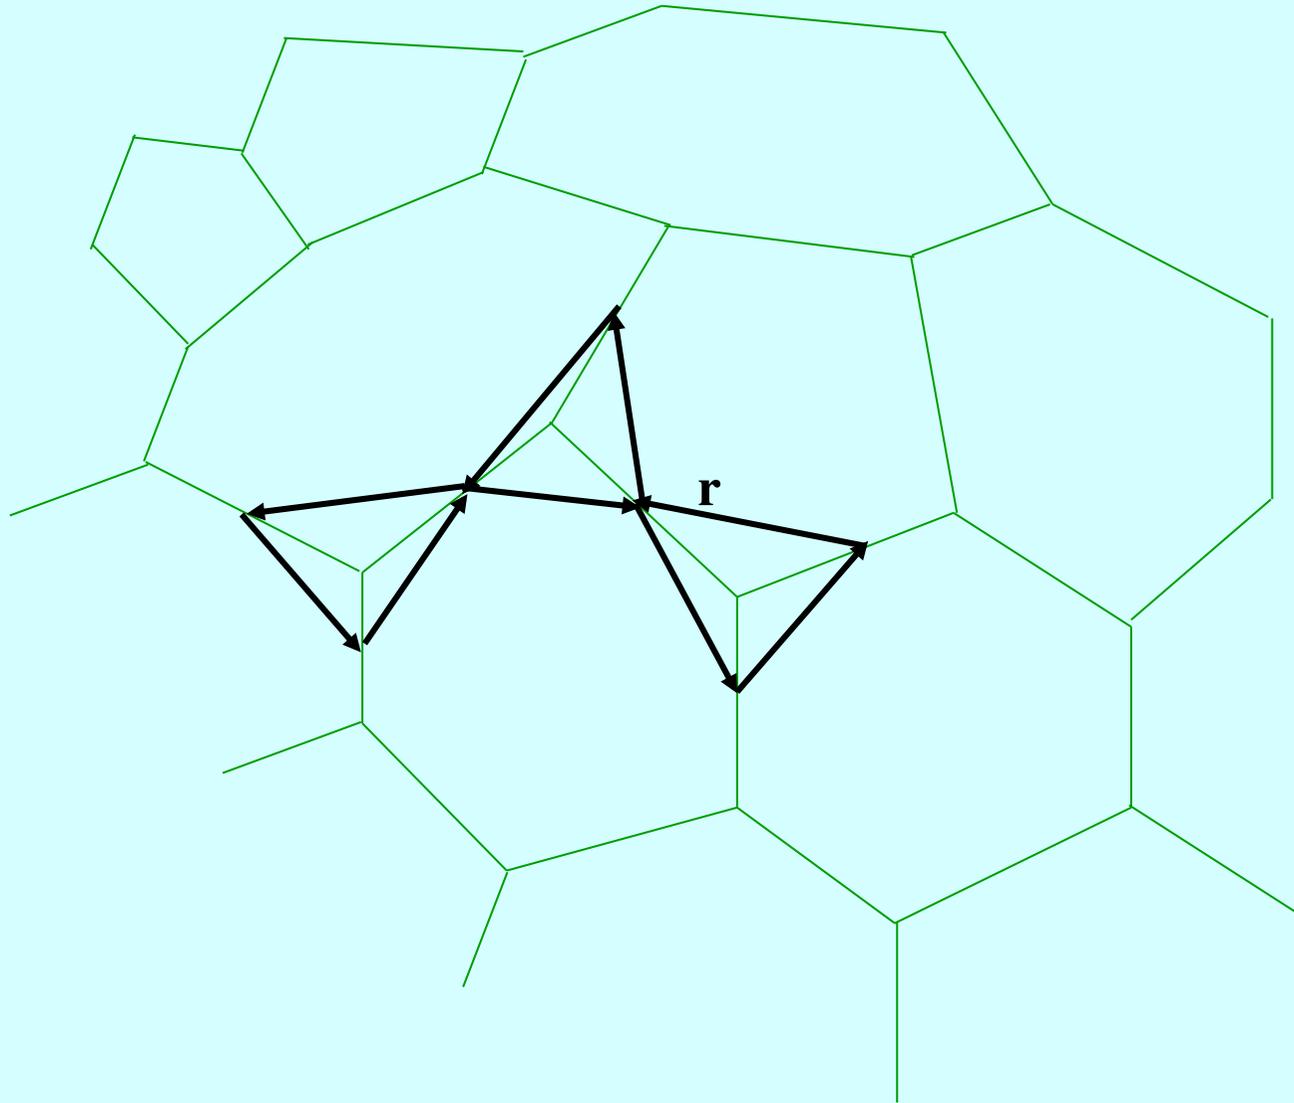

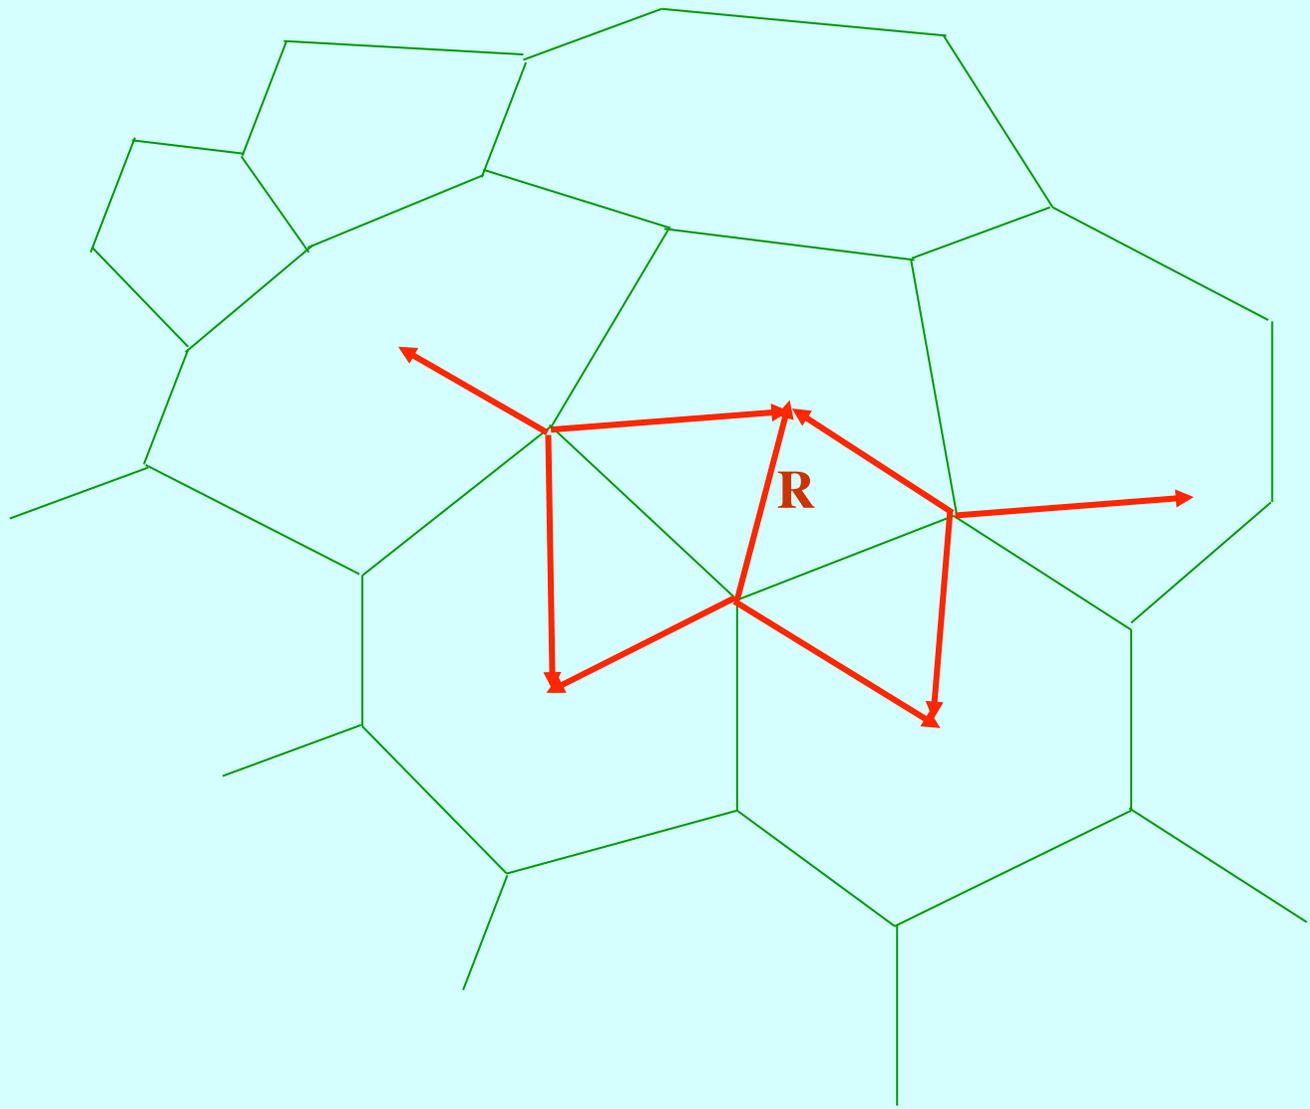

*Rafi Blumenfeld*

## Synopsis:

- Brief description of the characterisation method
- The method's advantages
- Aim of presentation:  
Looking for a collaboration to explore potential application to early detection of metastasis risk

# Quantifying the structure – quadron construction

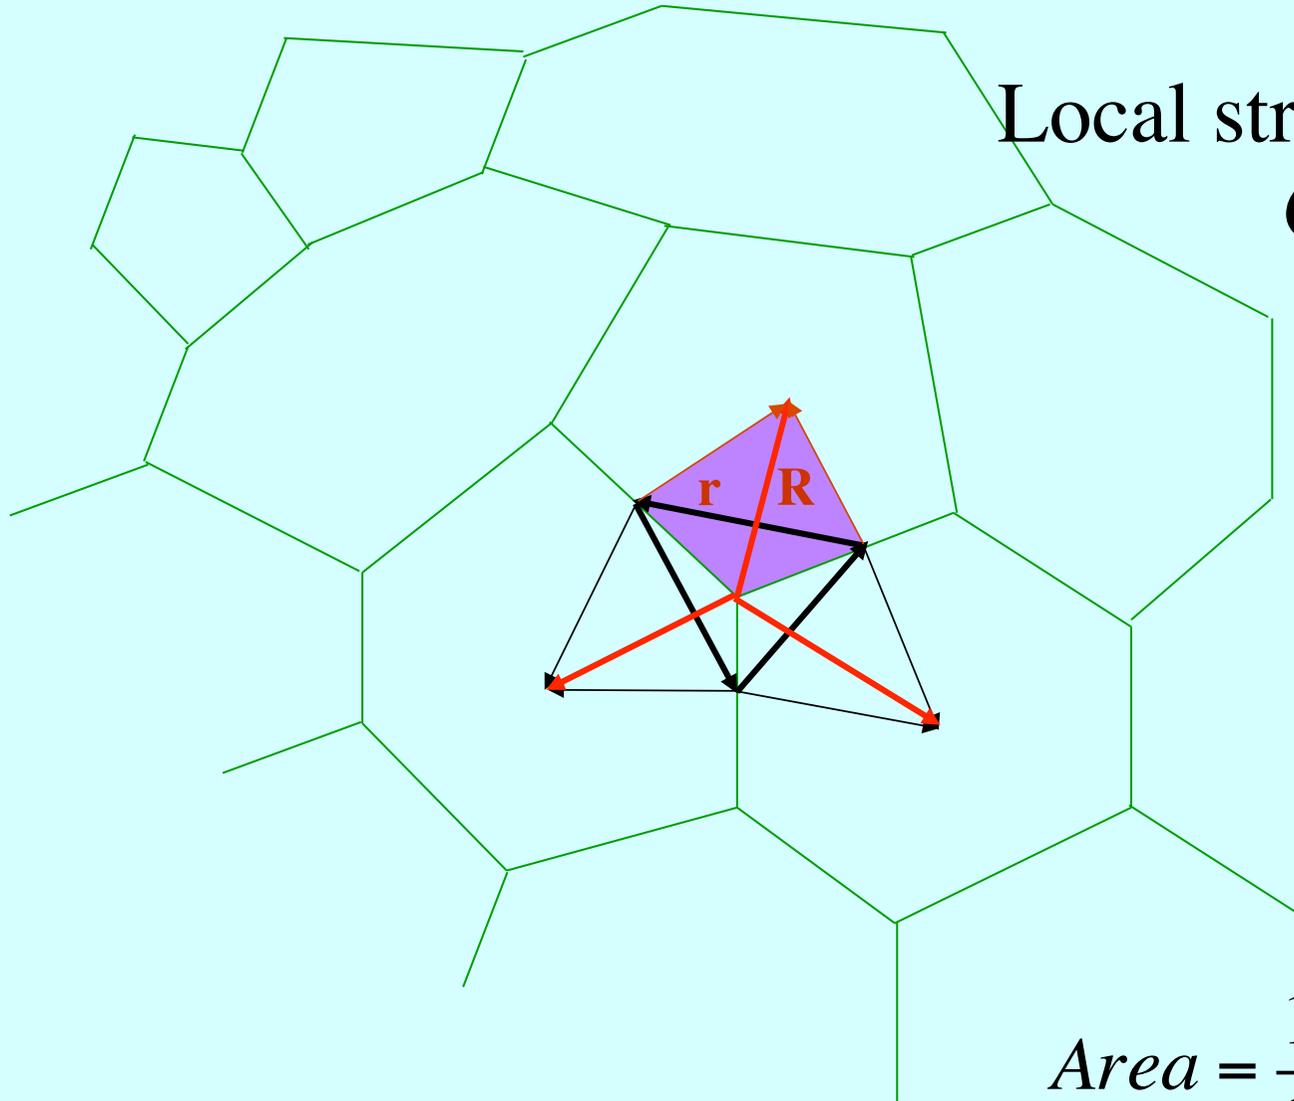

# Quantifying the structure – structure tensor

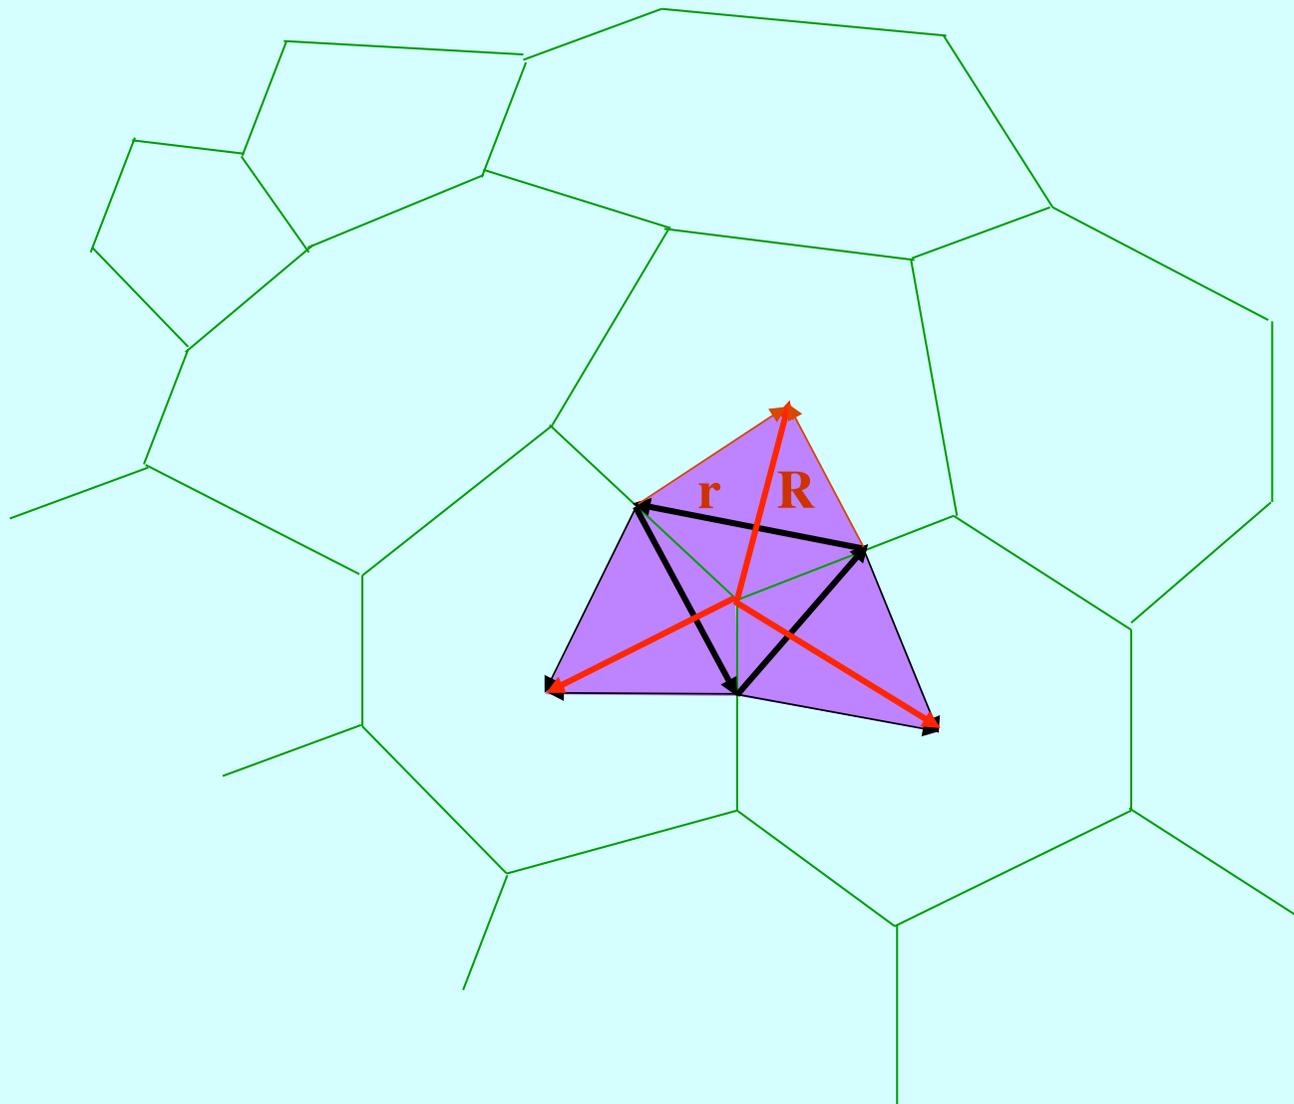

Local structure tensor

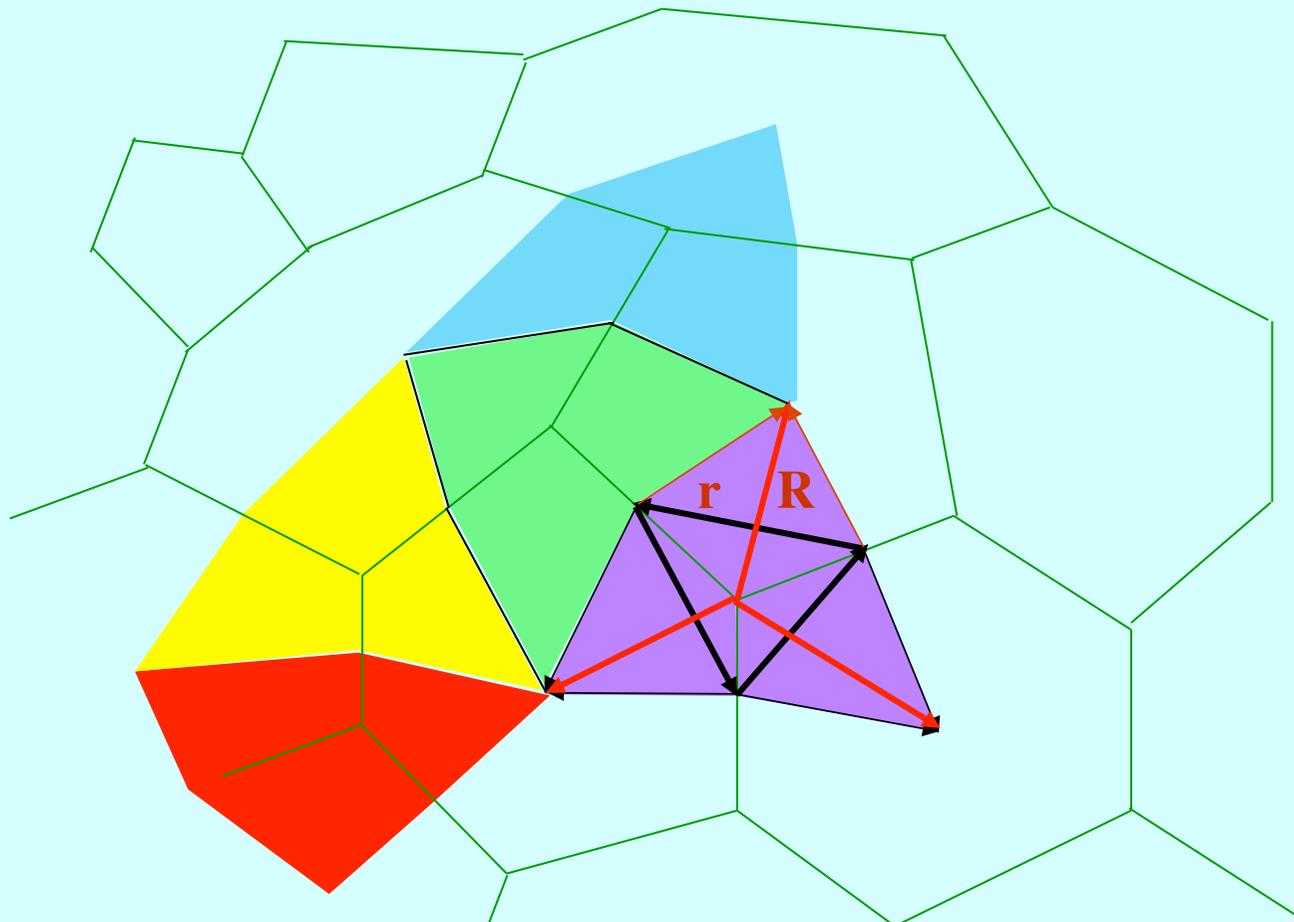

$$C_{ij} = r_i R_j$$

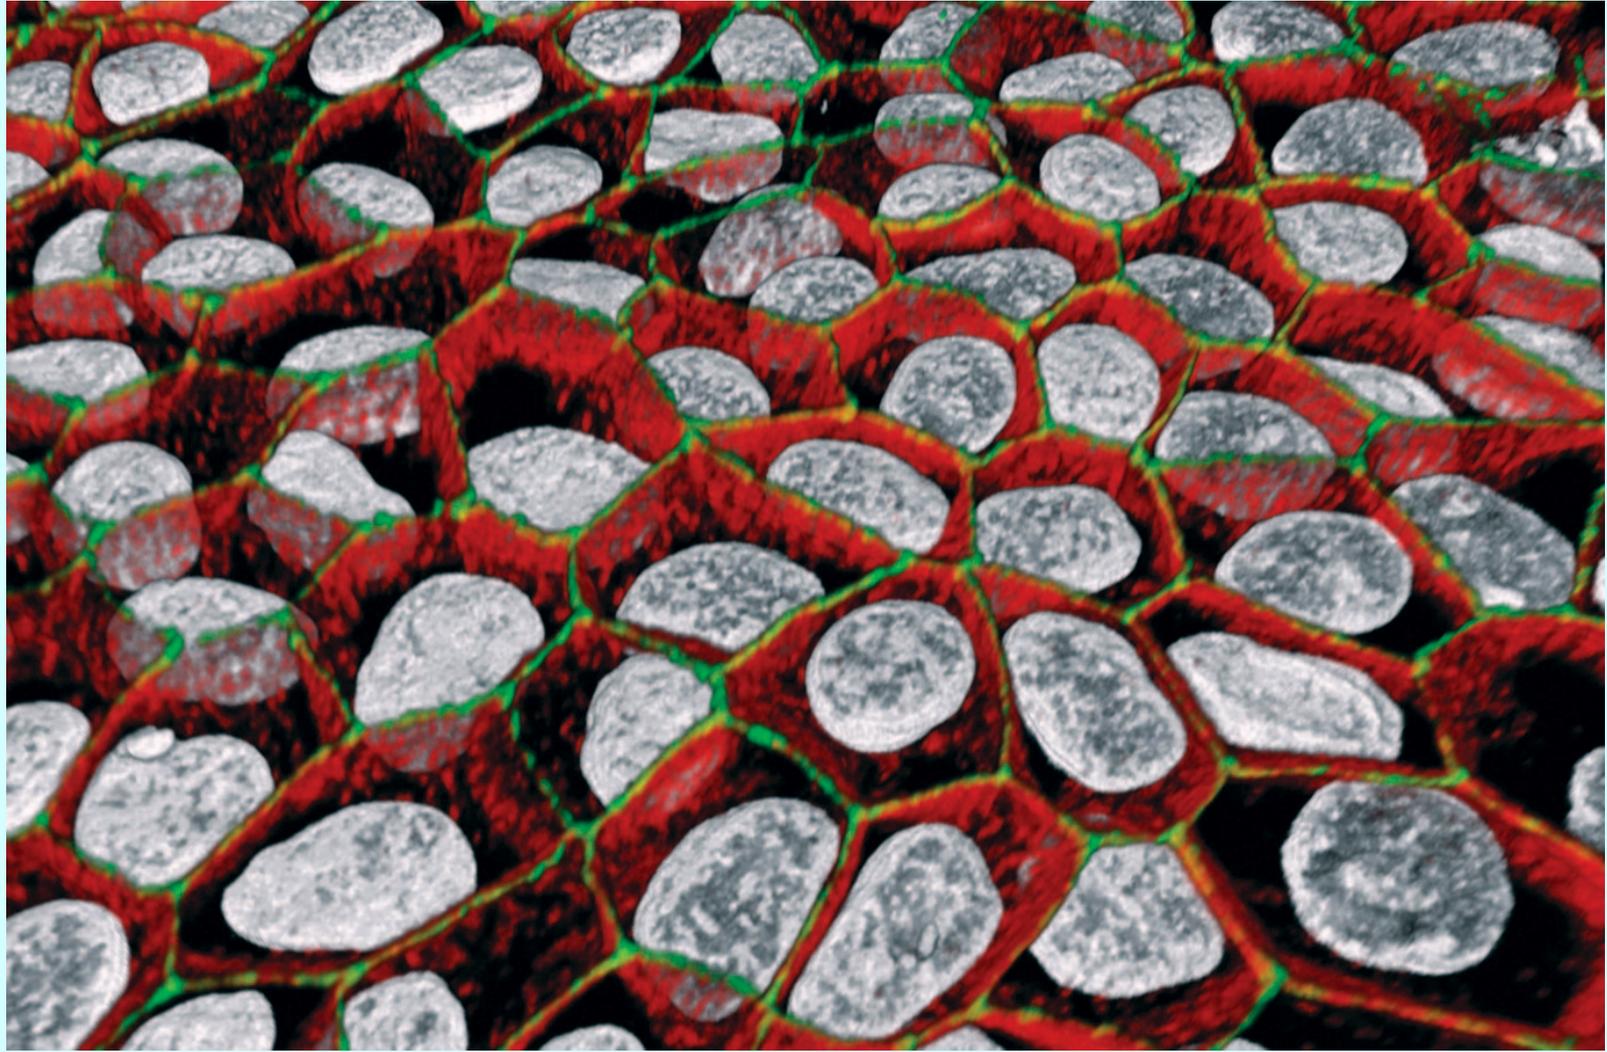

$$Area = \frac{1}{2}(r_x R_y - r_y R_x)$$

# Quantifying the structure – tiling the space

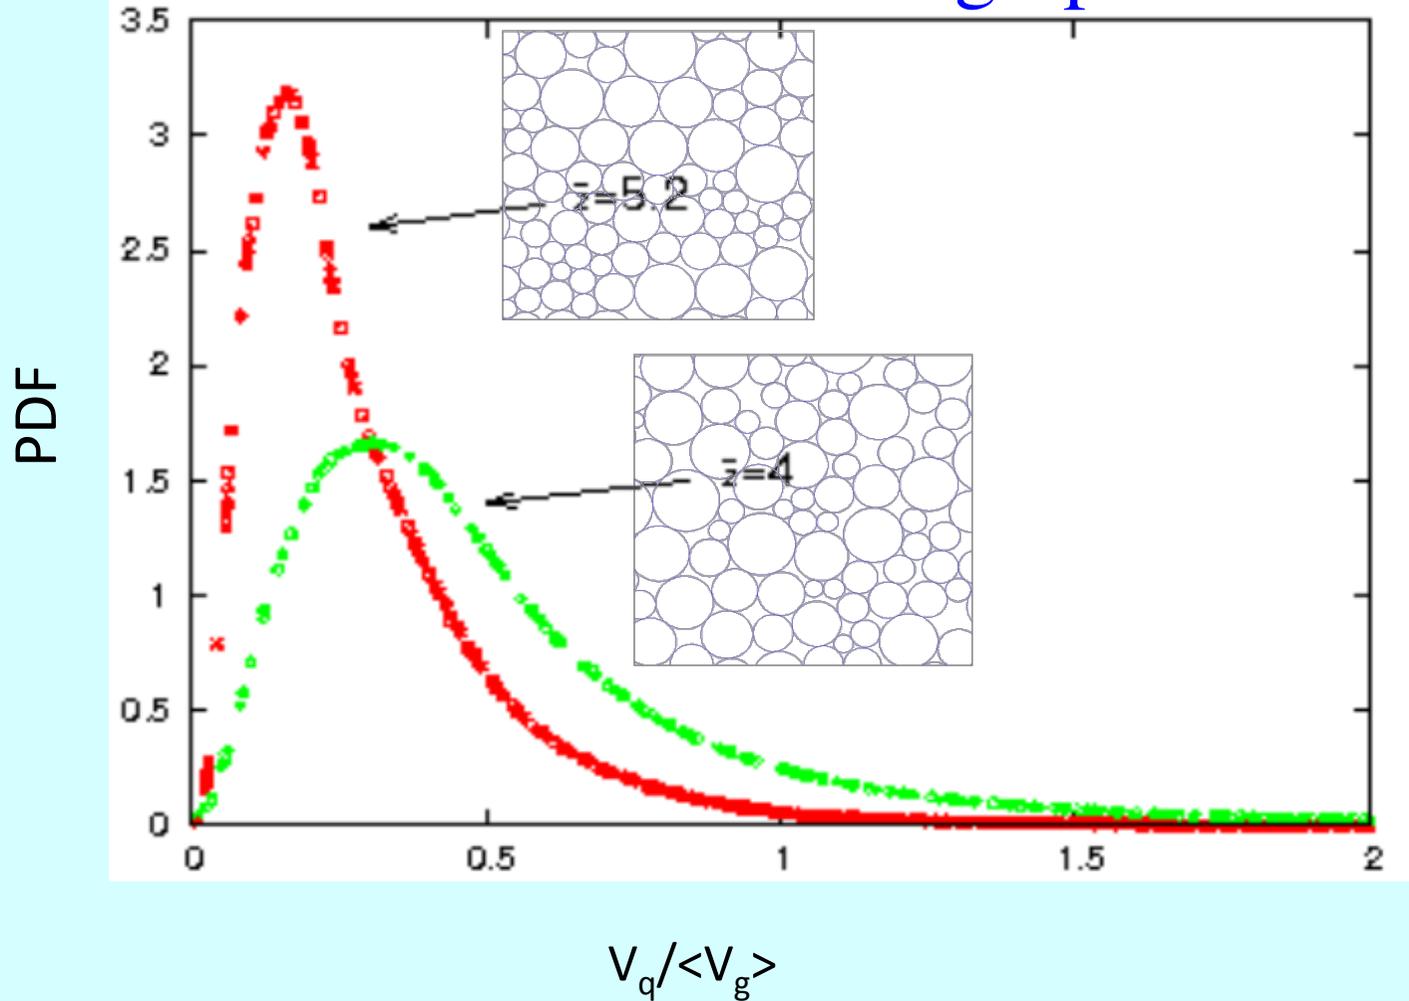

1. Tile the entire cellular structure and quantify the structure at every quadron.
2. Collect the statistics of quadron volumes (areas). Different systems have different statistics.

# The quadron volume distribution as a sensitive structural fingerprint - 2d

Same method in 3d - Comparison between two foam-like systems:

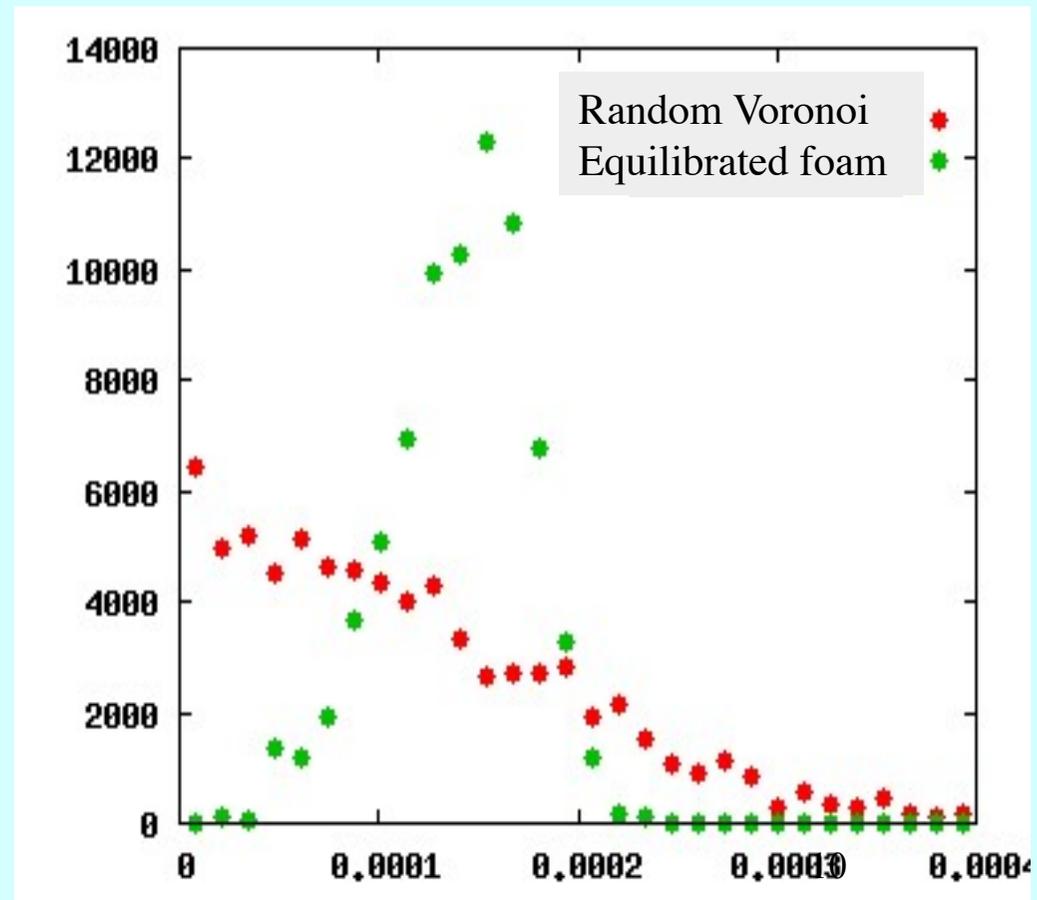

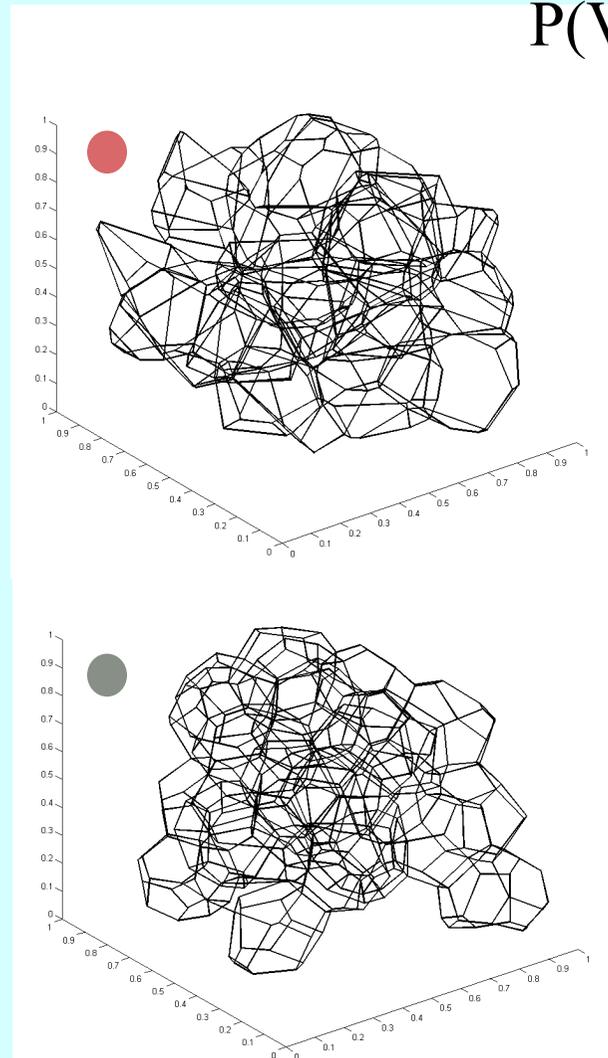

3d

Red - a system is generated from a random Voronoi tessellation;

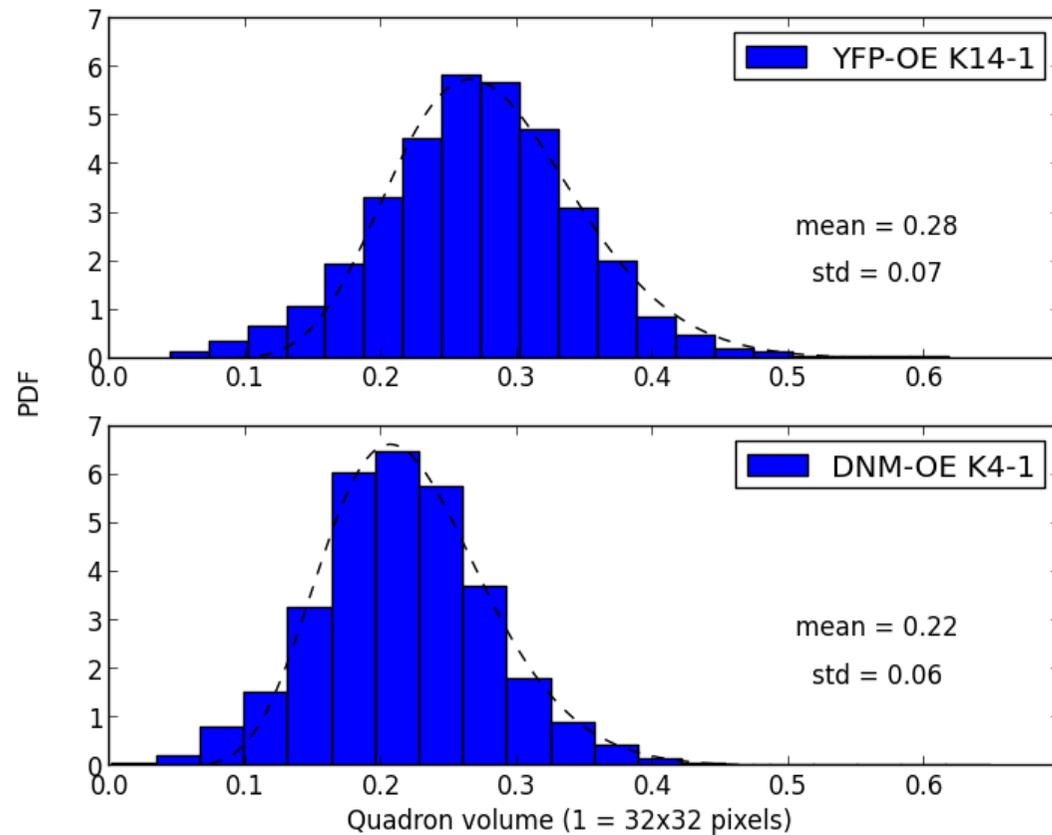

Green - the same system treated as a foam and evolved to minimise surface energy.

The distributions are completely different.

$P(V)$  is sensitive to the structure.

# Basal slices of normal and infected cell tissues

# Basal slices of normal and infected cell tissues

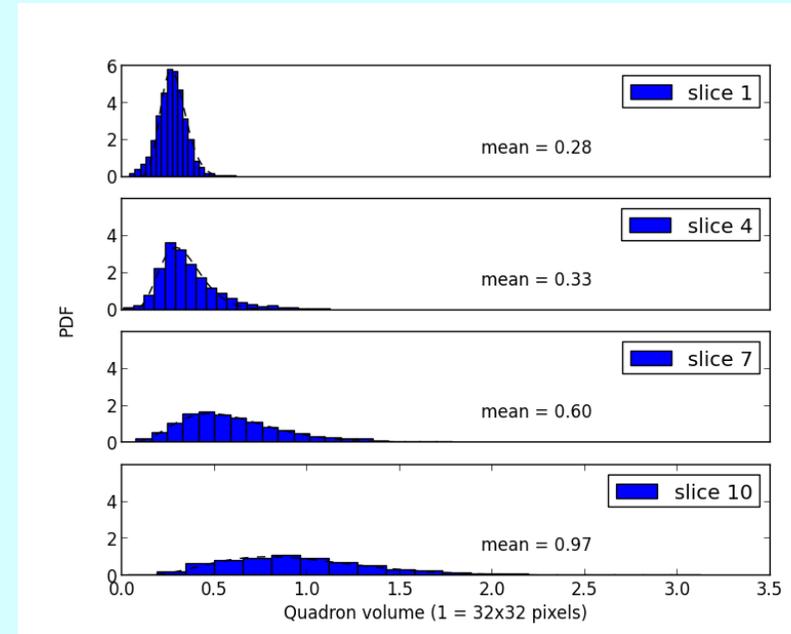

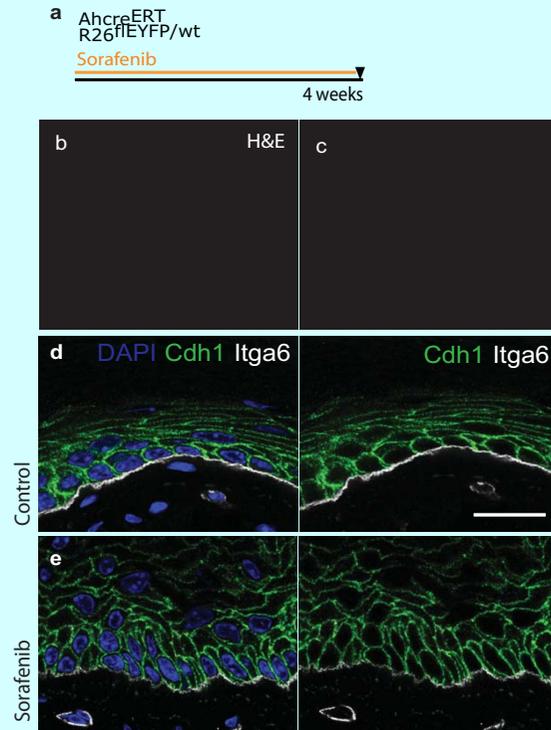

Figure 3 Characterization of effect of Sorafenib on cell morphology. (a) Protocol: Animals were treated with indicated doses of Sorafenib by ip injection for 28 days on alternate days. (b,c) H&E of OE for Sorafenib (b) and control treated animals (c). (d,e) Cryosections stained for Cadherin1 (green) and Itga6 (white). Scale bar, 20  $\mu$ m. (b) Animals treated with vehicle control. (c) Animals treated with Sorafenib.
